Education Gaps

1. It is important to recognize the risks for symptomatic patent ductus arteriosus. Infants born weighing more than 1,000 g or at more than 28 weeks’ gestation generally do not require pharmacologic or surgical intervention for patent ductus arteriosus.

2. Criteria that define patent ductus arteriosus pathophysiology need to be identified. Size of the ductus arteriosus alone is inadequate as a determinant when deciding whether to intervene pharmacologically or surgically. Criteria such as gestational age, postnatal age, and markers of hemodynamic significance, including degree of respiratory support, presence of oliguria, and other echocardiographic indicators, should be considered.

Abstract

Preterm infants are at increased risk for patent ductus arteriosus (PDA). Prolonged exposure to PDA may be deleterious and has been associated with neonatal morbidity and mortality. Although the molecular mechanisms underlying regulation of postnatal ductus arteriosus closure are not fully understood, clinical experience and research trials have informed recent changes in PDA management strategies and refocused treatment strategies on smaller subsets of infants who require intervention. This review examines current diagnostic and management approaches to PDA in preterm neonates.

Objectives

After completing this article, readers should be able to:

1. Explain the efficacy and associated side effects of the 3 pharmacologic agents (acetaminophen, ibuprofen, and indomethacin) used to treat a hemodynamically significant patent ductus arteriosus (PDA).

2. Identify clinical signs of a hemodynamically significant PDA.

3. Identify known risk factors for PDA in the preterm population.

4. Describe the characteristic echocardiographic features associated with a PDA and their sensitivity and specificity.

AUTHOR DISCLOSURE

Dr Gillam-Krakauer is supported, in part, by the Katherine Dodd faculty scholars program from the Department of Pediatrics, Vanderbilt University Medical Center. Dr Reese has disclosed an NIH award (HL128386). This commentary does not contain a discussion of an unapproved/investigative use of a commercial product/device.

NT-proBNP N (amino)-terminal prohormone of B-type natriuretic peptide
PDA patent ductus arteriosus
INTRODUCTION

The ductus arteriosus is a central vascular shunt connecting the pulmonary artery to the aorta, allowing oxygenated blood from the placenta to bypass the uninnflated fetal lungs and enter the systemic circulation. Rapid closure of the ductus arteriosus after birth is essential for vascular transition to the mature, divided pattern of arteriovenous circulation. Failure of ductus arteriosus closure, termed patent ductus arteriosus (PDA), is primarily an affliction of prematurity, with the ductus remaining open at 7 days of age in up to 64% of infants born at 27 to 28 weeks’ gestation and 87% of infants born at 24 weeks. (1) There has been a shift in presentation and treatment of infants with PDA over the past 30 years. (2) (3) Before the use of antenatal corticosteroids, PDA was frequently found in premature infants of all gestational ages and was associated with respiratory distress syndrome. Treatment with indomethacin was standard, and studies evaluated the benefits of early (or even prophylactic) PDA ligation. (4)

With advances in ventilation strategies, use of antenatal corticosteroids and exogenous surfactant, and increased willingness to wait for spontaneous ductus arteriosus closure, today’s more mature preterm infants rarely require intervention for a ductus arteriosus. (5) Instead, PDA management is now focused on the most premature infants, in whom the ductus can be resistant to pharmacologic treatment. This review discusses the evolving indications for treatment of a PDA and the various treatment options available.

RISK FACTORS

The incidence of PDA is inversely associated with the degree of prematurity. Other factors associated with an increased risk of PDA in the premature infant include respiratory distress syndrome, high volume of intravenous fluids (>170 mL/kg per day) in the first week, sepsis, prolonged rupture of membranes, furosemide, male sex, and other contributors. (6) Evidence also shows that aminoglycoside antibiotics and certain antacids, frequently used in neonates, paradoxically increase the risk of a PDA. (7) Antenatal corticosteroids (8) and maternal hypertension (9) decrease the incidence of PDA. The effect of antenatal corticosteroids on closure of the ductus arteriosus is independent of their effect on lung maturation, and is most beneficial when corticosteroids are administered at least 24 hours before delivery. (10) Exogenous surfactant does not directly affect the ductus arteriosus, but can unmask a patent ductus by decreasing the pulmonary vascular resistance and thus allowing for increased left to right shunting. (1)

DIAGNOSIS

A consensus definition for hemodynamically significant PDA is lacking. The diagnosis is often suspected clinically, when an infant demonstrates signs of excessive shunting from the arterial to pulmonary circulation (Fig 1A and 1B):

- Continuous or systolic murmur; note, a “silent” PDA may also occur when the ductus shunt is large enough that nonturbulent flow fails to generate a detectible murmur.
- A low diastolic blood pressure (due to runoff into the ductus during diastole, more frequent in the most premature infants)
- A wide pulse pressure (due to ductus runoff or steal)
- Hypotension (especially in the most premature infants)
-Bounding pulses
-Increased serum creatinine concentration or oliguria
-Hepatomegaly

Signs of pulmonary edema are often seen, including tachypnea, decreased oxygen saturation, and increasing respiratory support. Chest radiography can show stigmata of pulmonary edema. The neonatal cardiac output can increase as much as 25% in an effort to overcome ductus steal. (11)

Clinical suspicion should be confirmed with echocardiography (Table 1). Ductus size alone is inadequate to attribute hemodynamic significance. Although an absolute transductus diameter of more than 1.5 to 1.7 mm by color Doppler (Fig 1C and 1D) has been associated with increased propensity for hypoperfusion, the exact diameter at which hemodynamic significance will occur varies by patient and postnatal age, depending on body size and many other factors, including oxygen saturation, surfactant administration, and furosemide. (12) El Hajjar et al suggest that by normalizing to body weight, a ductus diameter of more than or equal to 1.4 mm/kg is a more sensitive measure. (13)

A large left-to-right shunt suggests a hemodynamically significant shunt. However, the degree of shunting depends in large part on pulmonary vascular resistance. A large ductus may not demonstrate large left-to-right flow if pulmonary vascular resistance is increased. In contrast, a right-to-left shunt may indicate significant pulmonary hypertension; acute closure of the ductus in this scenario is not indicated, because it could result in worsening right heart failure. With a large left-to-right shunt, indirect signs of obligatory pulmonary hypertension may often be seen; this generally is not a contraindication to closure of the ductus but rather a natural consequence of excessive pulmonary blood flow.

Other echocardiographic criteria used to determine hemodynamic significance are the presence of reversal of
forward flow in the descending aorta during diastole (indicating shunting through the PDA), and left atrial or ventricular dilation, which are the consequence of over-circulation of the pulmonary vascular bed and a chronic hyperdynamic state. Left-to-right flow across the intra-atrial septum is indicative of a large shunt. The ratio of the left ventricular output to superior vena cava flow is directly proportional to the ductus flow and, when greater than or equal to 4, may indicate hemodynamic significance. A left atrial to aortic root (LA/Ao) ratio is most sensitive when performed after day 1, and is considered abnormal if greater than 1.5. For comparison, the ductus is considered widely patent when the LA/Ao ratio is greater than 1.6, and closed when the ratio is 1.17. (14) If a cutoff of 1.4 is used, sensitivity of the LA/Ao ratio drops from 88% to between 50% and 79%. (14)(15)

PDA severity scores have been developed that combine various factors and can be used to predict higher likelihood of serious outcomes, such as death/chronic lung disease (CLD), periventricular leukomalacia, or necrotizing enterocolitis (NEC). The benefit of a scoring system is that it emphasizes the importance of examining multiple
factors when determining when and whether to intervene for a PDA. Table 2 shows a comparison of 2 separate scoring systems. Although they use different factors, they are equivalent in defining a hemodynamically significant PDA and prediction of CLD or death. The El-Khuffash score correlates significantly with NEC and the Shaare Zedek score correlates significantly with periventricular leukomalacia. (16)

Biomarkers
The N (amino)-terminal prohormone of B-type natriuretic peptide (NT-proBNP) and mature B-type natriuretic peptide (BNP) may be useful in detecting a hemodynamically significant PDA. BNP is secreted and released by the ventricular myocardium when under stress from either increased volume or pressure. NT-proBNP, BNP, and cardiac troponin rise with increase in echocardiographic markers of PDA, and decrease following closure of the ductus. Not enough studies have been conducted to recommend these biomarkers for routine use in clinical management of a PDA. (17) They are likely to be of most benefit when the diagnosis of PDA is confirmed with echocardiography, but serial echocardiography to determine hemodynamic significance is unavailable, (12) or to shorten a course of pharmacologic treatment for a ductus. Shin et al stopped treatment with ibuprofen in infants with a PDA when BNP concentration dropped to less than 600 pg/mL, resulting in fewer doses of ibuprofen in the group whose treatment was tailored based on BNP. (18)

OUTCOME
In healthy full-term infants, the ductus arteriosus closes within 48 to 72 hours. In premature infants born weighing more than 1,000 g, the ductus closes spontaneously in 67% by day 7 and in 94% by discharge. (5) Overall, only 3% of infants weighing more than 1,000 g may require intervention for a PDA. (1)(5) However, in extremely premature infants weighing less than 1,000 g at birth (extremely low birthweight), 57% to 69% will still have a PDA at 7 to 10 days of age. (5)(9) Of those that close, up to 30% will reopen and may then reclose, or go on to become hemodynamically significant and require pharmacologic or surgical closure. When left untreated, the median time to ductus closure in this population is 56 days. (5) Some infants undergo spontaneous ductus closure as late as 24 months of age. (29)(30) Although these infants only account for a small proportion of premature infants and have small PDAs at the

Biosensors
Bioengineering and analytical techniques have also been developed to monitor or detect PDA in preterm infants. Various approaches include interpretation of pulse oximetry information (perfusion index, plethysmography), (19)(20) (21) interpretation of transthoracic electrical signals (impedance, cardiometry, velocimetry, bioreactance), (22)(23)(24) (25) regional oxygenation (near-infrared spectroscopy), (26) alterations in skin microcirculation (side stream darkfield imaging, reflectance spectrophotometry), (27)(28) resonance Raman spectroscopy (Lauren J. Ruoss, personal communication, May 2018), and others.
time of discharge, (31) the recognition that PDA closure occurs late in some cases has prompted some investigators to completely withhold retreatment. (32)(33) Because hemodynamically significant PDA has been associated with intraventricular hemorrhage (IVH), pulmonary hemorrhage, NEC, CLD, (9) and death, more substantial studies are required before nonintervention approaches can be widely adopted.

**TREATMENT**

Some clinicians choose a prophylactic approach to indomethacin treatment, with a goal of preventing IVH, PDA, and the adverse consequences that have been associated with PDA in extremely low-birthweight infants. (34) Despite successful reduction in short-term outcomes (IVH, pulmonary hemorrhage, hypotension, symptomatic PDA, need for ligation), long-term benefits are uncertain and infants may needlessly be exposed to a potentially harmful agent. (3)(35) (36)(37)(38)(39) On the other hand, NICUs with consistent, high-level use of a prophylactic strategy (40) or an echocardiography guided selective approach to prophylactic treatment (41) may have improved outcomes or less drug exposure. Well-designed studies are needed to clarify the risks/benefits of this approach.

The indications for treatment of a symptomatic PDA include respiratory compromise (eg, requiring persistent mechanical support), heart failure, or large left-to-right ductus shunt with evidence of hemodynamic compromise, such as reversal of flow in the descending aorta during diastole, oliguria or rising serum creatinine concentration, hypotension, or wide pulse pressure.

In patients of more than 1,000 g birthweight with few risk factors, a PDA can generally be successfully managed conservatively, with modest fluid restriction and use of positive end expiratory pressure to treat pulmonary edema. Certain diuretics, such as furosemide, can prevent a ductus from closing (42) and are not recommended in the first 1 to 3 weeks, when the greatest decrease in ductus diameter occurs spontaneously. Conservative measures also include avoidance of other drugs that promote ductus arteriosus relaxation (43) and proactive use of agents like caffeine that are associated with lower rates of PDA. (44)

In patients at higher risk of PDA, or who weigh less than 1,000 g at birth, conservative treatment is recommended before starting pharmacologic treatment. Treatment is generally not necessary in the first few days after birth when the pulmonary vascular resistance is still elevated. However, during the second week, treatment should be considered if conservative measures have failed to control pulmonary edema, or if there is cardiac or renal failure. After week 3, pharmacologic measures are less likely to be successful.

Early use of indomethacin to close a PDA soon after birth (day 1–2 of age), compared with waiting 3 to 4 days after diagnosis, decreases the risk for pulmonary hemorrhage and IVH, and need for ligation. Although PDA is associated with CLD, there is limited evidence to suggest that early pharmacologic closure improves incidence of CLD. (40)(45) Pharmacologic closure is associated with decreased pulmonary edema and improved alveolarization (in premature baboons). This may be due at least in part to a direct effect on the lung. Use of ibuprofen or indomethacin is associated with increased amiloride-sensitive alveolar epithelial sodium channels, increased lung water clearance, and improved lung compliance. (45)

**PHARMACOLOGY**

Three pharmacologic treatments are available to induce constriction of a PDA: indomethacin, ibuprofen, and acetaminophen (paracetamol) (Table 3). Indomethacin and ibuprofen are classic nonsteroidal anti-inflammatory drugs (NSAIDs), which nonselectively inhibit the cyclooxygenase enzymes, preventing the conversion of arachidonic acid to prostaglandins, which play a central role in maintaining ductus patency. Since 1976, indomethacin has been used to treat PDA in premature infants. Around the same time, ibuprofen was shown in lamb models to effect ductal closure but it was not widely used in human infants until the mid-1990s. Acetaminophen reduces prostaglandin synthesis by a different mode of action than most NSAIDs. Recent randomized clinical trials confirm its efficacy for PDA closure, though Food and Drug Administration approval for this indication is pending.

Indomethacin is administered intravenously. Enteral and rectal preparations are not recommended in infants because of increased risk for gastrointestinal bleeding.

In patients who receive a second course of indomethacin, only half will experience ductus closure. The odds of nonresponse to the second course of indomethacin are increased by 90% if there was nonresponse to the first course. Advancing gestational age appears to predict nonresponse to indomethacin. (46)

When studied head-to-head, indomethacin and ibuprofen have a similar efficacy (75%) for an initial course of 3 doses. Regardless of the treatment, there is about a 25% rate of reopening, especially in the most premature infants. Because of this high rate of reopening, some advocate a fourth dose of indomethacin, given 24 hours after the third dose.

Acetaminophen is speculated to decrease prostaglandin synthesis by disrupting prostaglandin synthesis at the
peroxidase site of prostaglandin H2 synthetase (cyclooxygenase). Acetaminophen for treatment of PDA is associated with less elevation in serum creatinine concentration and oliguria compared to ibuprofen or indomethacin, and less elevation in bilirubin compared to ibuprofen. (47) Acetaminophen has been used for rescue therapy after failed response to indomethacin in extremely premature infants, resulting in 46% of infants having a smaller or closed ductus. (48) When used as primary treatment, the efficacy ranges from 70% to 81%. (49)(50) Efficacy appears to be affected by both gestational age and postnatal age, with improved efficacy noted when treatment was started within the first week. (51) In fact, many case reports describing the use of acetaminophen start treatment as early as 2 to 3 days of age, early enough that many patients may go on to experience complete closure. Ductus closure rates are lower for the 3-day course (56%). (49)

There is a range of reported treatment regimens for acetaminophen, from 7.5 mg to 10 or 15 mg/kg every 6 hours for 3 to 7 days. Acetaminophen can be given orally, at the same dosage and interval, with similar reported efficacy as the intravenous route. (49) Kessel et al (52) showed that paracetamol levels in infants of age 26 to 30 weeks treated with 15 mg/kg per day orally remained mostly within the recommended range of 10 to 20 mg/mL for analgesia before the fifth and ninth doses, with only 2 of 8 patients exceeding the desired range before the ninth dose.

Treatment with acetaminophen can be associated with increase in serum concentration of liver enzymes in children and adults. This has been reported in preterm infants after as few as 4 doses of 15 mg/kg per day. Spontaneous resolution has been reported in all cases after the cessation of acetaminophen administration. Immaturity of the hepatic CYP enzymes responsible for acetaminophen metabolism may be protective against short-term toxicity in preterm infants; however, caution is warranted because liver injury is still possible. (53)

Whether or not to withhold enteral nutrition when a patient has a significant PDA or during pharmacologic treatment has long been a source of practice variability. A hemodynamically significant PDA can reduce forward blood flow to the superior mesenteric artery during diastole, and indomethacin acutely decreases gut blood flow. On the other hand, fasting is associated with intestinal mucosal atrophy which could increase the risk for NEC. A trial of premature infants being treated with indomethacin or ibuprofen and randomized to either receive 15 mL/kg of feeds per day or fast during treatment showed no difference in rates of NEC, and the patients randomized to continue

feedings reached full feeds earlier than infants whose feeds were held. (54)

LIGATION

Surgical ligation is performed when a neonate has a hemodynamically significant PDA that results in cardiac dysfunction, renal failure, or respiratory failure. Ligation is typically performed with an open thoracic approach, and either using a metal clip or tying off the vessel. Intravascular approaches with placement of an occluding coil are available for patients weighing more than 5 kg. Trials are under way with products in development to accomplish catheter-based PDA closure in smaller patients. (55)

PDA ligation is associated with many adverse effects: vocal cord paralysis, postoperative hypotension, diaphragm paralysis, (56) bronchopulmonary dysplasia, and worse neurodevelopment. (57) Early PDA ligation is an independent risk factor for BPD (45) and worse neurodevelopment compared with ligation at a later age. (58) There does not appear to be increased risk of major complications when infants who have failed indomethacin treatment but do not have cardiopulmonary compromise are treated conservatively, rather than treated with ligation. (59) However, poor outcomes after PDA ligation may be overestimated by trial design, (60) suggesting that surgical approaches deserve full consideration for infants with refractory, symptomatic PDA.

CONCLUSION

PDA remains an important condition among premature infants born at less than 28 weeks’ gestation. Recent advances include the addition of acetaminophen (paracetamol) to the arsenal of available treatments, and further support for conservative management of the asymptomatic or mildly symptomatic PDA, before the consideration of pharmacologic treatment. Improvements are still needed regarding standardized echocardiographic criteria, optimal timing of treatment (when indicated), dosing regimens for acetaminophen, and development of endovascular occlusive devices for the smallest preterm infants.

American Board of Pediatrics Neonatal-Perinatal Content Specifications

- Recognize the clinical features of a preterm neonate with a patent ductus arteriosus.
- Recognize the laboratory, imaging, and other diagnostic features of a preterm neonate with a patent ductus arteriosus.

Formulate a differential diagnosis of a preterm neonate with a patent ductus arteriosus.

Know the evaluation and medical and/or surgical management and associated potential complications or adverse effects of such management for a preterm neonate with a patent ductus arteriosus.
